

Appendix: Uniform Binary Variables

In this appendix, we consider the case in which each variable x_i , $i = 1, \dots, n$, takes values in $\{-1, 1\}$, and the marginal distribution over each x_i induced by p is uniform. This can be viewed as a coarsening of an underlying Gaussian distribution, such that x_i records the sign of a Gaussian variable.

We do not have a complete analysis of our problem for this specification of p , and focus on the chain model $1 \rightarrow 2 \rightarrow \dots \rightarrow n$. In Eliaz et al. (2019), we provided a characterization of the maximal estimated correlation that such a model can generate in a uniform-binary environment. The proof was by induction on n . Here we give a constructive proof that emphasizes the analogy with the Gaussian case. Our analysis is based on a few preliminary observations.

Definition 1 *A $n \times n$ matrix C is called “Binary Factorizable” (BF) if it can be written as*

$$C = \lim_{M \rightarrow \infty} \frac{1}{M} A_M A_M^T$$

Where each A_M is a $n \times M$ matrix whose elements are all ± 1 and each row of A_M is zero mean.

Note that any BF matrix is symmetric, positive semi-definite, and has ones on the diagonal. Note also that any covariance matrix of zero-mean binary random variables must be BF, since we can define the matrix A_M as a sample covariance matrix, where the sample consists of M *i.i.d* draws from the underlying distribution. The converse is also true: any BF matrix corresponds to the covariance matrix of zero-mean binary random variables. This can be seen by defining a distribution over n binary variables by randomly picking (with probability $1/M$) one of the columns of A_M .

Somewhat surprisingly, however, there exist symmetric, positive semi-definite matrices which are *not* BF. For example, the reader may recall the following correlation matrix from the example in the Introduction, where it

gave the maximal false correlation for $n = 3$ in the Gaussian environment:

$$C = \begin{pmatrix} 1 & b & 0 \\ b & 1 & b \\ 0 & b & 1 \end{pmatrix}$$

with $b = \sqrt{1/2}$. This matrix is *not* BF. As we will see below, the largest value of b for which C is BF is $\frac{1}{2}$.

Proposition 1 *Suppose all variables take values in $\{-1, 1\}$ and the objective distribution p induces a uniform marginal over each variable. Let the objective (Pearson) coefficient of correlation between x_1 and x_n , according to p , is r . Then, the maximal estimated correlation that can be achieved by a linear DAG $G : 1 \rightarrow 2 \rightarrow \dots \rightarrow n$ is given by:*

$$\rho_{1n}^* = \max_{\substack{\rho_{ij} = \rho_{ji} \text{ for all } i, j \\ (\rho_{ij}) \text{ is BF} \\ \rho_{ii} = 1 \text{ for all } i \\ \rho_{1n} = r}} \prod_{i=1}^{n-1} \rho_{i, i+1}$$

Proof. The constraints are self-evident. We only need to show that for a linear DAG defined over uniformly distributed binary variables, the estimated correlation between x_1 and x_n is given by the product of the objective pairwise correlations of adjacent variables (as in the Gaussian case). We can show this by viewing $p_G(x_1, \dots, x_n) = p(x_1)p(x_2 | x_1) \cdots p(x_n | x_{n-1})$ as a Markov chain. The conditional probability $p_G(x_n | x_1)$ is thus given by a matrix product - specifically, the product of all the transition matrices defined by $p(x_{i+1} | x_i)$. Since all variables are uniformly distributed, the transition matrices are doubly stochastic, which means that they have the same eigenvectors. The top eigenvalue is always 1 and the second eigenvalue gives the correlation. Since all matrices have the same eigenvectors, the eigenvalues just multiply. ■

Note that Proposition 1 is exactly the same as the intermediate result we established at the beginning of Section 4.3 for the Gaussian environment. The only difference is that we replace the requirement that ρ be positive

semi-definite with the requirement that ρ be BF. As mentioned above, the set of BF matrices is smaller than the set of positive semi-definite matrices. Therefore, we should expect a more stringent upper bound on the maximal false correlation.

Proposition 2 *Suppose all variables take values in $\{-1, 1\}$ and the objective distribution p induces a uniform marginal over each variable. Let the objective (Pearson) coefficient of correlation between x_1 and x_n , according to p be equal to r . Then, the maximal estimated correlation that can be generated by the DAG $1 \rightarrow 2 \rightarrow \dots \rightarrow n$ is given by:*

$$\rho_{1n}^* = \left(1 - \frac{1}{n-1}(1-r)\right)^{n-1} \quad (1)$$

Proof. From Proposition 1, we know that the maximal estimated correlation is obtained by multiplying elements in a BF correlation matrix (ρ_{ij}) such that $\rho_{1n} = r$. For any $n \times M$ matrix A_M , let $a_i^{(M)}$ denote its i^{th} row. Then, we can rewrite the estimated correlation induced by $C_M = \frac{1}{M}A_M A_M^T$ as:

$$\prod_{i=1}^{n-1} \frac{1}{M} a_i^{(M)T} a_{i+1}^{(M)}$$

As we discussed following the definition of BF matrices, the dot product between the i^{th} and j^{th} rows of A_M is proportional to the empirical correlation of x_i and x_j in a sample consisting of M *i.i.d* draws from the underlying distribution.

Given a matrix A_M that gives an objective correlation of $\rho_{1n} = r$, we can always attempt to improve the estimated correlation by optimizing all other rows of the matrix a_2, \dots, a_{n-1} . This implies that for any M :

$$\rho_{1n}^* \leq \max_{a_2, \dots, a_{n-1} \in \{-1, 1\}^M, a_1 = a_1^{(M)}, a_n = a_n^{(M)}} \prod_{i=1}^{n-1} \frac{1}{M} a_i^T a_{i+1} \quad (2)$$

This is an upper bound for two reasons. First, we are not enforcing the constraint that the binary vectors a_i are zero mean. Second, if $C = \frac{1}{M}A_M A_M^T$

for some finite M , then C is BF.

For binary vectors $a_i, a_j \in \{-1, 1\}^M$, the dot product $\frac{1}{M}a_i^T a_j$ is a monotone function of the proportion q of components for which the two vectors agree: $\frac{1}{M}a_i^T a_j = 2q - 1$. Thus, maximizing the dot product between two binary vectors is equivalent to minimizing the number of components on which they disagree. This means that the R.H.S of (2) is a form of a *shortest path on a lattice*: we are given two points in $\{-1, 1\}^M$ (a_1 and a_n), and seek a set of intermediate points on this lattice that are as close as possible to each other. By analogy, in the third step of our proof for the Gaussian case, we were also given two vectors in a high-dimensional space (an n -dimensional unit sphere) and searched for a set of intermediate points on the sphere such that the intermediate points are as close as possible to one another (in terms of spherical distance).

To solve this “shortest path on a lattice” problem, we divide the M indices into two disjoint groups: M_1 indices k for which $a_1(k) = a_n(k)$ and M_{-1} indices k for which $a_1(k) \neq a_n(k)$. For any of the M_1 indices for which $a_1(k) = a_n(k)$, setting $a_i(k) = a_1(k)$ for all i can only increase the objective function (since this can only increase the dot product between consecutive vectors).

For the remaining M_{-1} indices k for which $a_1(k) \neq a_n(k)$, denote by m_i the number of indices k for which $a_i(k) = a_1(k)$ and $a_i(k) \neq a_n(k)$. Assuming $m_i > m_j$, the dot product between a_i and a_j can be written as follows:

$$a_i^T a_j = M - 2(m_i - m_j)$$

This enables us to rewrite (2) as:

$$\rho_{1n}^* \leq \max_{m_2, \dots, m_{n-1}} \prod_{i=1}^{n-1} \frac{1}{M} (M - 2(m_{i-1} - m_i)) \quad (3)$$

The R.H.S. of (3) should be maximized subject to the constraint that $m_i \in \{0, 1, \dots, M_{-1}\}$, but we can get an upper bound by maximizing over real-valued m_i .

Taking the logarithm of the R.H.S of (3) and differentiating with respect

to m_i yields that at an optimum, m_i should be linearly spaced between m_1 and m_n :

$$m_i - m_{i+1} = \frac{M_{-1}}{n-1}$$

Thus, the optimal shortest path is a set of binary vectors whose components agree with x_1 and x_n whenever they coincide, and the rest of the indices agree with x_1 with a fraction that decreases linearly with i .

Now, for large M , M_{-1}/M converges to the probability that $x_1 \neq x_n$, namely $\frac{1-r}{2}$, such that

$$\frac{1}{M} a_i^T a_{i+1} \rightarrow \left(1 - \frac{1}{n-1}(1-r)\right)$$

Since there are $n-1$ such dot products, we take their product, thus obtaining the R.H.S of (1).

To show that the upper bound is tight, given two uniform binary random variables x_1, x_n that satisfy $E(x_1 x_n) = r$, consider a set of variables x_i , whose distribution conditional on x_1, x_n is defined as follows:

- If $x_1 = x_n$, then $x_i = x_1 = x_n$.
- If $x_1 \neq x_n$, then $x_i = x_1$ with probability $1 - \frac{i}{n}$ and $x_i = x_n$ with probability $\frac{i}{n}$.

By construction, a vector of M random samples from x_i and x_{i-1} will generate a normalized dot product $\frac{1}{M} a_i^T a_{i+1}$ that converges to $\left(1 - \frac{1}{n-1}(1-r)\right)$ when $M \rightarrow \infty$, thus attaining the upper bound.

It is also worth noting that in Eliaz et al. (2019), we implement the upper bound by taking the n variables to be the sign of the Gaussian variables we used in the implementation of the upper bound of our the main theorem. ■

Let us illustrate the upper bound. For $n = 3$ and $r = 0$, the maximal estimated correlation between x_1 and x_3 using the chain model $1 \rightarrow 2 \rightarrow 3$ is $\frac{1}{4}$ (compared with the value $\frac{1}{2}$ in the Gaussian case). Finally, for any r , the maximal estimated correlation converges to e^{r-1} as $n \rightarrow \infty$ (compared with 1 in the Gaussian case).
